

APPENDIX C

Technical Methods - Derivation of Chinook Management Objectives and Fishery Impact Modeling Methods

Appendix C1.

Basis for Puget Sound chinook salmon escapement goals used in determining the harvestable abundance for Alternative 2. Several of these goals were also used as standards to evaluate the predicted effects of the alternatives when they represented the best information available about the habitat capacity and productivity of the watershed in which the chinook salmon population spawns.

Nooksack early

The management unit escapement goal of 4,000 early chinook salmon implies a goal of 2,000 natural-origin early chinook salmon spawners in each of the South Fork and North Fork Nooksack Rivers. The goal is not based on current habitat capacity, or the current productivity of either population. This interim goal was established in the 2001 Harvest Management Plan (WWIT and WDFW 2001).

Skagit Summer-fall and spring – Escapement goals are defined as the level, within the framework of the Puget Sound Chinook Harvest Management Plan, most likely to maximize long-term harvest. Escapement goals were derived analytically, based on recent productivity parameters derived by the Ecosystem Diagnosis and Treatment (EDT) method (Mobrand Biometrics 1999), assuming current habitat conditions. The population simulation model and methodological assumptions are described in detail in Appendix A to the HMP, Skagit River Management Unit Profile. (Note: The HMP is Appendix A to the DEIS.) The summer-fall chinook salmon escapement goal is 14,500; i.e. 8,434 for the upper Skagit summer population, 1,926 for the lower Sauk summer population, and 4,140 for the lower Skagit fall population. The spring chinook salmon escapement goal is 2,000, comprised of 986 for the upper Sauk, 440 for the Cascade, and 574 for the Suiattle populations. These goals are considerably higher than the MSY escapement levels calculated from spawner recruit parameters, without consideration of management error or environmental variation.

Stillaguamish – The escapement goal for the North Fork Stillaguamish (600) is an estimate of optimum (Maximum Sustained Yield) escapement, derived from fitting a Ricker recruitment function to recent spawner – recruit data. Cohort reconstruction of brood-year recruitment was calculated from coded-wire tag recoveries. The goal for the South Fork Stillaguamish (300) resulted from habitat-based analysis (EDT method – Mobrand Biometrics 1999; and Mobrand 2000) of the performance of various life history trajectories in the watershed given current habitat conditions. The output represents the average performance of the population under the given conditions, and there is no adjustment for random fluctuations or for improvements or degradation of habitat conditions. Additionally, average

marine survival conditions for 1989–1995 were assumed in this analysis (personal communication with Kit Rawson, Tulalip Department of Natural Resources, Senior Fishery Management Biologist, December 6, 2002). A Beverton-Holt recruitment function was fit to habitat-based productivity estimates, allowing a determination of escapement at Maximum Sustained Yield.

Snohomish – The Snohomish system escapement goal of 4,600 is a composite of population goals for the Skykomish (3,600) and Snoqualmie (1,000) systems. These goals were derived by the Ecosystem Diagnosis and Treatment method, described above for the Stillaguamish analysis. The Skykomish goal was verified using coded-wire-tag (CWT)-based cohort reconstruction, and spawner-recruit analysis. See the Puget Sound Chinook Harvest Management Plan, Appendix A, Snohomish River Management Unit Profile, for a detailed description of the derivation of these goals.

Lake Washington

The Lake Washington management unit escapement goal of 1,550 comprises goals for the Cedar River and Bear Creek of 1,200 and 350, respectively. The Cedar River escapement goal should be considered a conservative estimate. The goal is based on historical escapement estimates where an attempt is made to survey the entire known spawning area. However, in some years, chinook salmon adults spawn in tributaries to the Cedar River that are not usually part of the major spawning area. In addition, some fish are missed by the surveyors as they raft the river (personal communication with Steve Foley, Washington Department of Fish and Wildlife, Fisheries Biologist, February 18, 2004). The Bear Creek escapement goal is based on spawner counts in index reaches that have not been expanded to include chinook spawners in other known spawning areas of the river. They are based on historical counts in these areas, specifically the 1965–1969 average for the Cedar River, and the 1983–1992 average for Bear Creek. These interim goals were stated in a technical memorandum to WDFW and tribal managers (P. Hage, R. Hatch, and C. Smith. March 28, 1994. *Interim escapement goals for Lake Washington chinook salmon*). This goal was used to assess predicted impacts to escapement among the alternatives.

Green-Duwamish

The escapement goal of 5,800 for the Green – Duwamish River is based on survey of the index reach from RM 29.6 to 47.6 (17.4 stream miles). Accurate escapement estimates from this reach were expanded to the total system according to the distribution of total escapement determined from tagging

1 studies. Corrected total escapements for the 12-year period from 1965 to 1976 averaged 5,740, so the
2 system escapement goal was set at 5,800 (Washington Department of Fisheries Technical Report 29).

3 **White**

4 The interim escapement goal for the White River is for 1,000 adult chinook salmon to be captured at
5 the Buckley Trap and transported above Mud Mountain Dam. These fish then migrate to natural
6 spawning areas in the upper watershed. This goal was established by the inter-agency White River
7 Recovery Team (WDFW et al. 1996. *Recovery Plan for White River Spring chinook salmon*). It is
8 based on an analysis of habitat capacity (Warren 1994) in three tributaries to the upper mainstem, in
9 which the majority of natural spawning now occurs. This goal was used to assess predicted impacts to
10 escapement among the alternatives.

11 **Puyallup**

12 The current intent of fisheries management, for Puyallup fall chinook salmon, is to achieve escapement
13 of at least 500 into the South Prairie/Wilkeson Creek tributary system. While the relationship between
14 escapement to South Prairie and the entire Puyallup River system is not yet exactly quantified, the best
15 available information suggests this level of escapement to South Prairie Creek represents an index of
16 adequate seeding of the entire system. Uncertainty persists regarding system capacity due to the
17 difficulty in enumerating adult chinook salmon in the mainstem, and the unknown potential of recently
18 re-colonized habitat upstream of Electron Dam. For the purposes of catch modeling done for NEPA
19 review, a system escapement goal was established at 1,200. This estimate is based on analysis of
20 productivity under current habitat constraints, using the EDT method, which indicated that Maximum
21 Sustained Yield (MSY) escapement is approximately 600, assuming a 50 percent hatchery contribution
22 to natural spawning yields the escapement goal for the system.

23 **Nisqually**

24 Based on EDT habitat analysis, fitting a Beverton-Holt function to existing data on current habitat
25 potential, Maximum Sustained Yield escapement, under current conditions, was estimated to be 1,100
26 (NCRT 2001, Chapter 5, p. 46, and Appendix 4 Section 3.2).

27 **Skokomish and Mid- Hood Canal**

28 Current natural escapement goals for the Skokomish River, and the three Mid-Canal rivers
29 (Dosewallips, Duckabush, and Hamma Hamma) are 1,650 and 750, respectively. These goals are based

on the historical average escapement from 1965–1976 (WDFW 1977 Technical Report 29). The current capacity of habitat in these systems has not been quantified. Spawning habitat in the South Fork Skokomish is severely degraded and subject to annual flood or high flow. Hydroelectric facility operations constrain spawning success in the North Fork Skokomish.

Dungeness

The Dungeness River escapement goal of 925 is based on accessible spawning habitat (i.e., 17.7 miles in the mainstem, 8.0 miles in the Gray Wolf River), historical redd density (12 redds per mile), and spawner distribution (three adults per redd) (C. Smith and B. Sele. July 12, 1994. *Memorandum: Dungeness River escapement goal*). This goal was used to assess predicted impacts to escapement among the alternatives.

Elwha

The escapement goal for the Elwha River (2,900) is a composite of 2,400 adults required for broodstock by the hatchery programs, and 500 natural spawners. The natural component is based on the capacity of habitat that currently exists in the 4.9 river miles below Elwha Dam.

Hoko

The Hoko River escapement goal of 1,050 comprises the broodstock requirement for the Hoko Hatchery supplementation program of 200 (100 pairs), and 850 natural spawners to adequately seed natural spawning habitat in the mainstem and tributaries (Washington Department of Fisheries Technical Report 29).

Appendix C2.

Basis for National Marine Fisheries Service Critical and Viable Escapement Thresholds, and Rebuilding Exploitation Rates used to assess the effects on abundance and recovery of Puget Sound chinook salmon populations.

The method used to determine critical and viable escapement thresholds and Rebuilding Exploitation Rates was developed with three objectives in mindⁱ. This method is described in more detail by NMFS in a document titled Viable Risk Assessment Procedure (McElhaney et al. 1999). First, NMFS sought to evaluate the proposed fisheries using biologically-based measures of the total exploitation rate that occurred across the full range of the species. Second, NMFS sought to use an approach that was consistent with the concepts developed by NMFS' Northwest Fisheries Science Center for the purpose of defining the conservation status of populations and ESUs; i.e., Viable Salmonid Populations (McElhaney et al. 1999). Finally, NMFS sought to develop an approach for defining target exploitation rates that could be related directly to the regulatory definition of jeopardy. The product of this approach is a set of Rebuilding Exploitation Rates for representative stocks within each Evolutionarily Significant Unit. Rebuilding Exploitation Rates were developed for a limited set of Puget Sound chinook salmon populations. The proposed fisheries were then evaluated, in part, by comparing the Rebuilding Exploitation Rates to exploitation rates anticipated as a result of the proposed fishery regime, recognizing that the jeopardy determination must be made with respect to the overall ESU. More qualitative considerations were used to extrapolate where necessary from the available Rebuilding Exploitation Rate analyses.

There are four steps involved with determining population-specific Rebuilding Exploitation Rates: 1) identify populations, 2) set critical and viable threshold abundance levels, 3) estimate population productivity as indicated by a spawner-recruit relationship, and 4) identify an appropriate Rebuilding Exploitation Rate through simulation.

As described in Subsection 3.3, Fish – Affected Environment, the population structure used for the Puget Sound chinook salmon Evolutionarily Significant Unit is that defined by the Puget Sound and Olympic Peninsula Technical Recovery Team (Puget Sound Technical Recovery Team 2003).

ⁱ This method was first used to assess the impacts from implementation of the Pacific Salmon Treaty (NMFS 1999) and has been used by NMFS to evaluate harvest actions impacting the Puget Sound chinook salmon ESU since that time (NMFS 2000 [PFMC BO], NMFS 2001 [4(d) Rule]).

1 The Viable Salmonid Populations document (McElhaney et al. 1999) develops the idea of threshold
2 abundance levels as one of several indicators of population status (others being productivity, spatial
3 structure, and diversity). The thresholds described include a critical threshold and a viable population
4 abundance level. The critical threshold generally represents a boundary below which uncertainties
5 about population dynamics increase and therefore extinction risk increases substantially. The viable
6 population threshold is a higher abundance level that would generally indicate recovery or a point
7 beyond which ESA-type protections are no longer required, with the caveat that abundance is not the
8 only relevant or necessary indicator of recovery.

9 The Viable Salmonid Populations document provides several rules of thumb that are intended to serve
10 as guidelines for setting population-specific thresholds (McElhaney et al. 1999). Unfortunately, these
11 guidelines continue to evolve as part of the ongoing development process. Population-specific targets
12 will be identified in the final recovery plan for the Puget Sound chinook salmon ESU. However,
13 because the thresholds were needed to set the Rebuilding Exploitation Rates, NMFS considered the
14 existing rules of thumb, and other relevant guidance, to make preliminary threshold determinations for
15 Puget Sound chinook salmon populations.

16 The critical threshold was developed from a consideration of genetic, demographic, and spatial risk
17 factors for each population. Genetic risks to small populations include the loss of genetic variation,
18 inbreeding depression, and the accumulation of deleterious mutations. The risk posed to a population
19 by genetic factors is often expressed relative to the effective population size, or the size of an idealized
20 population that would produce the same level of inbreeding or genetic drift that is seen in an observed
21 population. Guidance from the existing Viable Salmonid Populations document suggests that effective
22 population sizes of less than 500 to 5,000 per generation are at increased risk. The population size
23 range per generation was converted to an annual spawner abundance range of 125 to 1,250 by dividing
24 by four, which is the approximate generation length. An escapement level of 200 fish was selected
25 from this range to represent a critical threshold for genetic risk factors (Method 1), since most of the
26 populations that were subject to the Rebuilding Exploitation Rate analysis were relatively small. For
27 example, the interim escapement objectives for the Nooksack River stocks are 2,000 fish each. Critical
28 escapement threshold values much larger than 200 would be out of context for the populations of
29 concern.

30 The Biological Requirements Work Group (BRWG 1994) took genetic considerations and other factors
31 into account in their effort to provide guidance with respect to a lower population threshold for Snake

1 River spring/summer chinook salmon. They recommended annual escapements of 150 and 300, for
2 small and large populations, which represented levels below which survival becomes increasingly
3 uncertain due to various risk factors and a lack of information regarding population responses at low
4 spawning levels. This provides independent support for the use of 200 (which is within the range of
5 150 to 300) as a critical threshold.

6 Factors associated with demographic risks include environmental variability and depensation.
7 Depensation – a decline in the productivity of a population (e.g., smolts per spawner) as the abundance
8 declines – can result from the uncertainty of finding a mate in a sparse population and/or increased
9 predation rates at low abundance. Demographic risks were assessed using a Ricker stock-recruit model
10 (Method 2). Peterman (1977 and 1987) provided a rationale for depensation and suggested relating the
11 escapement level at which depensation occurs to the size of the population in the absence of fishing
12 (equilibrium escapement level). NMFS set this measure of the critical threshold equal to 5 percent of
13 the equilibrium escapement level. In cases where there were no data in the lower range of escapements,
14 a third method (Method 3) was used. In these cases, the lowest escapement with a positive adult return
15 was used.

16 Each of the measures of the preliminary critical threshold was considered in the context of the types
17 and quality of data available, the characteristics of the watershed, and the biology of the population
18 (Table C2-1). For “large populations,” NMFS typically selected a critical threshold based on Method 2
19 to assure a sufficient density of spawners, or Method 3 where there were no escapements in the lower
20 range to define the lower limb of the stock-recruit relationship. Method 1 was used for small
21 populations or populations for which NMFS was unable to estimate the equilibrium population size or
22 analysis is not complete at this time.

23 Similar methods were used to establish the viable population threshold. In this case, the criteria were
24 1,250 spawners (genetics, derived from the Viable Salmonid Population guideline range of 5,000 to
25 16,700 divided by the average generation length of approximately 4 years) (Method 1); the level of
26 escapement required to achieve the maximum sustainable yield (demographics) under current
27 environmental conditions (Method 2); or other information related to the productivity and capacity of
28 the watershed (Method 3). Again, the decision concerning which method to use was based on a
29 consideration of the context of the types and quality of data available, the characteristics of the
30 watershed, and the biology of the population (Table C2-1).

1 The third step in the process of identifying population-specific Rebuilding Exploitation Rates is to
2 estimate the stock-recruit parameters. Estimates of the stock-recruit parameters for each population
3 were required for both establishing the escapement threshold levels (Method 2), and for the simulations
4 of population dynamics. Several different stock-recruit relationships were examined: Ricker, Beverton-
5 Holt and the Hockey Stick. The three functions differ primarily in the response of population
6 abundance at higher escapement levels. The Ricker function assumes that at some level of spawners,
7 productivity begins to decline as escapement increases; i.e., at higher escapement levels, competition
8 for natural resources (such as spawning or rearing space and food) results in fewer progeny produced
9 for each additional spawner. The Beverton-Holt function assumes that at some level of escapement,
10 productivity continues to increase with increasing escapement, but only gradually. The Hockey-Stick
11 function assumes that at some level of escapement, productivity levels off, neither increasing nor
12 decreasing. Below this level of escapement, the relationship is density-independent; i.e., the number of
13 progeny produced is independent of the number of spawners. Where data were sufficient to conduct
14 spawner-recruit analyses, hatchery-origin spawners were included in the estimate of parent escapement
15 since they contributed to the progeny produced, but were removed from the escapement of adults
16 produced from that brood year in order to assess the natural productivity of the parental spawners.

- 1 Figure C2-1. Spawner-recruit response for each spawner-recruit function evaluated in development of
2 escapement thresholds and Rebuilding Exploitation Rates.

- 3
4 The final step in determining Rebuilding Exploitation Rates is to use a simulation model to iteratively
5 solve for an exploitation rate that meets specific criteria related to both survival and recovery given the
6 specified thresholds and estimated spawner/recruit parameters. The consultation regulations define
7 "jeopardize the continued existence" to mean:

- 8 "... to engage in an action that reasonably would be expected, directly or indirectly, to reduce
9 appreciably the likelihood of both the survival and recovery of a listed species in the wild by
10 reducing appreciably the reproduction, numbers, or distribution of the species" (50 CFR section
11 402.2).

1 The simulation then uses a quantified level of risk associated with this definition - "... reduce
2 appreciably the likelihood of survival and recovery ..." and the population specific threshold levels to
3 identify an exploitation rate that meets the following criteria:

4 1) Did the percentage of escapements less than the critical threshold value increase by less than 5
5 percentage points relative to the baseline?

6 and, either

7 2a) Does the escapement at the end of the 25-year simulation exceed the viable threshold at least 80
8 percent of the time?

9 or

10 2b) Does the percentage of escapements less than the viable level at the end of the 25-year simulation
11 differ from the baseline by less than 10 percentage points?

12 For comparison purposes, these simulations were measures against simulations that assumed these
13 species were not harvested anywhere as the baseline (a zero exploitation rate). In addition, the
14 simulation model uses available information on management error, and errors in measurement of the
15 stock-recruit parameters used in the model to account for uncertainty in management precision and
16 parameter estimation.

17 The Rebuilding Exploitation Rate is then the level of exploitation rate that results in a low probability
18 that the proposed harvest action will endanger the survival of the population, and a relatively high
19 probability that the proposed harvest action will not impede recovery as defined in this context.
20 Recovery in this context means achieving the viable abundance threshold for a population, assuming
21 current habitat conditions. That is why they are called Rebuilding and not Recovery Exploitation Rates.
22 Recovery will require improvements in all primary sources of salmon mortality. A separate recovery
23 planning process is currently underway that will ultimately define recovery in terms of necessary
24 improvements in all four Hs (harvest, hatchery, habitat and hydropower), and in the context of the ESU
25 as a whole.

26 The Rebuilding Exploitation Rate is the highest exploitation rate that can meet Criterion 1 and
27 Criterion 2a or 2b. Once identified, proposed fisheries can be evaluated by considering the likelihood
28 that they will meet the Rebuilding Exploitation Rates. It is important to emphasize that the Rebuilding
29 Exploitation Rate analysis is made with respect to populations, while ESA determinations must be
30 made with respect to the anticipated impacts to the ESU. For example, failure to meet the Rebuilding

1 Exploitation Rate standards for one population in a large ESU such as the Puget Sound chinook salmon
2 ESU does not necessarily indicate jeopardy to the ESU as a whole.

3 A final step was to convert the Rebuilding Exploitation Rates based on coded-wire tags (CWT) into
4 values that could be easily compared with output from the model used to assess the alternatives in this
5 Environmental Impact Statement: the Fishery Regulation Assessment Model (FRAM). This step was
6 necessary to compare the exploitation rates resulting from the fishery strategies under each alternative
7 to the Rebuilding Exploitation Rates used to assess progress toward recovery. This was done by
8 regressing validated FRAM exploitation rates from past years against the brood year CWT-based
9 exploitation rates from which the Rebuilding Exploitation Rates were derived. The regression
10 relationship was then applied to the Rebuilding Exploitation Rate CWT-based value, resulting in a
11 Rebuilding Exploitation Rate measured in FRAM terms.

12 The RERs, CETs and VETs used in the DEIS, both those used as objectives and those used as
13 standards for evaluation, were derived from several methods depending on the amount and quality of
14 available data (DEIS Appendices A and C). For those populations where these parameters are derived
15 from population-specific spawner-recruit relationships, the parameters will change as changing habitat
16 conditions, both in marine and freshwater environments, are reflected in the spawner-recruit
17 relationship. A spawner-recruit relationship describes the number of fish at a given life stage that is
18 produced from a specific level of adult escapement (Figures C2-1 and C2-2), taking into account the
19 amount of available habitat (capacity), and the quality of the habitat (productivity). As described
20 previously in this section, the viable thresholds are generally defined as the number of spawners that
21 corresponds with the point of maximum sustained yield; i.e., the largest number of fish produced per
22 spawning adult. The critical thresholds are defined as the number of spawners that corresponds with
23 five percent of the equilibrium escapement (the number of progeny is equal to the number of spawning
24 adults), or as the lowest adult escapement that more than replaces itself in the subsequent generation. It
25 is important to remember that the term “viable threshold” as used by NMFS in the context of this EIS is
26 based on consistency with current habitat conditions and should not be confused with what would
27 represent a recovered population.

28 The spawner-recruit relationship for a population may change, and thus the escapement level
29 corresponding to the viable threshold will increase or decrease as habitat quality and quantity increase
30 or decrease (Figure C2-2). The same may or may not be the case for the critical threshold, since it
31 defines a minimal escapement more influenced by genetic and demographic concerns than the viable

1 threshold (Table C2-1). For example, an increase in habitat quality and quantity will not change the
2 critical threshold as defined by the lowest escapement that replaces itself. Increasing or decreasing
3 habitat capacity will have less of an effect on the number of offspring produced than increasing or
4 decreasing productivity and, when the number of spawners that the habitat can support increases, the
5 number of offspring (recruits) produced for each additional spawner may not increase without an
6 increase in habitat quality (Table C2-1 and Figure C2-2). Increasing or decreasing spawning or rearing
7 habitat capacity will result in a corresponding increase or decrease in the viable escapement threshold.
8 Increasing or decreasing habitat quality will have a larger effect on the number of offspring produced
9 per spawner at a lower viable escapement threshold than with changes in habitat capacity (Figure C2-
10 2). This is because, although the amount of habitat is limited, the quality of the habitat in terms of food,
11 water quality, or other factors influences the survival of the offspring produced much more than a
12 change in the amount of available habitat. The greatest change in the magnitude of the viable
13 escapement threshold and the offspring produced occurs when both the capacity and the quality of the
14 habitat changes.

15 Because the RER is dependent on the probability of meeting the viable and critical thresholds, it will
16 change as these thresholds change. In general, as the habitat improves or increases, the RER will
17 increase because more fish will be produced for each spawner and a greater surplus will be available
18 beyond that needed to sustain the population (Table C2-1). When habitat quality and quantity
19 decreases, the RER will decrease because less surplus will be available and the possibility of falling
20 below the critical threshold will become more likely.

Table C2-1. Changes in the viable escapement thresholds, the critical escapement threshold, and the available surplus as a function of changes in habitat capacity (carrying capacity in terms of number of smolts rather than area) and productivity. Productivity and capacity were increased or decreased by a factor of 2. These are examples only and do not represent an actual Puget Sound Chinook salmon population.

		<u>Capacity</u>		<u>Quality</u>		<u>Both</u>	
	<u>Control</u>	<u>Increase</u>	<u>Decrease</u>	<u>Increase</u>	<u>Decrease</u>	<u>Increase</u>	<u>Decrease</u>
<u>Viable Escapement Threshold</u>	<u>1,000</u>	<u>2,500</u>	<u>500</u>	<u>2,000</u>	<u>300</u>	<u>3,500</u>	<u>100</u>
<u>Critical Escapement Threshold</u>	<u>200¹</u>	<u>260</u>	<u>200¹</u>	<u>240</u>	<u>200¹</u>	<u>470</u>	<u>200¹</u>
<u>Offspring produced at VET</u>	<u>1,720</u>	<u>3,455</u>	<u>860</u>	<u>4,929</u>	<u>508</u>	<u>9,375</u>	<u>112</u>
<u>Recruits/spawner at VET</u>	<u>1.7</u>	<u>1.4</u>	<u>1.7</u>	<u>2.5</u>	<u>1.0</u>	<u>2.7</u>	<u>1.1</u>
<u>Surplus Available</u>	<u>720</u>	<u>1,460</u>	<u>360</u>	<u>2,930</u>	<u>8</u>	<u>5,880</u>	<u>0</u>

¹ The critical threshold is lower in these situations when calculated as 5% of the equilibrium abundance, but without evidence that the spawners could replace themselves at such a low level, a generic critical threshold of 200 based on the general scientific literature would be implemented.

Appendix C3. Modeling Assumptions and Inputs for EIS Alternatives and Scenarios

The effects on listed and unlisted salmon and socio-economic impacts evaluated in the Environmental Impact Statement were determined by the distribution and magnitude of catch, fishing opportunity (sport angler trips) and escapement. The Fisheries Regulation Assessment Model (FRAM) and other sources of data were used to predict catch, exploitation rates, angler trips and escapement. Results were reported for five regional fisheries consistent with the available FRAM model output:

Regional Fishery	Washington Catch Areas
Strait of Juan de Fuca	4B (except May-September when area is under the jurisdiction of the Pacific Fisheries Management Council), 5, 6, 6A, 6C Dungeness Bay (6D) All freshwater rivers flowing into the Strait of Juan de Fuca.
North Puget Sound	7, 7A Bellingham Bay (7B, 7C, 7D) All freshwater rivers flowing into these marine areas.
Central Puget Sound	8, , 8A, 9 Skagit Bay (8) Tulalip Bay (8D) All freshwater rivers flowing into these marine areas.
South Puget Sound	Marine areas 10,11,13, 13A-13K Elliott Bay (10A) Sinclair Inlet (10E) Commencement Bay (11A) Lake Washington and a freshwater rivers flowing into South Puget Sound marine areas.
Hood Canal	Marine areas 12, 12B, 12C Port Gamble Bay (9A) Quilcene/Dabob Bays (12A) All freshwater rivers flowing into these marine areas.

The following sections describes the assumptions made regarding the abundance of contributing salmon stocks and the structure of fisheries, in order to predict the catch and escapement of the five species of salmon associated with each alternative. As described below (C4), the FRAM allows a very detailed assessment of commercial and recreational harvest of chinook and coho salmon in Puget Sound, based on equally detailed input of expected stock abundance and the expected fishery regime, and predicts natural and hatchery escapement for management units or, with subsequent analysis, individual populations. Chinook catch and escapement were analyzed in greater detail (four scenarios), to consider the effects of variable northern (Canadian/Alaskan) intercepting fisheries and of variable abundance.

Fisheries for other species (i.e., pink, sockeye, coho, and chum salmon) are managed to achieve escapement goals established for management units. Their harvest distribution is analyzed in less detail because the structure of fisheries, which are primarily commercial, is much less complex. For species other than chinook salmon the effects of variable abundance were not modeled or described.

Catch and escapement for each species of salmon was reported for each Puget Sound management unit, with catch in regional fisheries detailed where applicable. Total exploitation rates were estimated for each management unit. Estimates of total mortality and escapement were also reported for hatchery and naturally-spawning components where applicable. Exploitation rates were assumed to be the same for hatchery- and naturally-spawning components since the information is not available to distinguish between the two components.

With the forecast abundance of hatchery production and natural components, and the expected catch in all fisheries as input, the FRAM estimates catch by fishery and escapement for individual management units of chinook and coho salmon. Catch was reported either as catch of all populations within a region, or catch of a management unit across all regional fisheries.

For management units with multiple populations, the exploitation rate for each population was assumed to be the same as that of the management unit because the available model does not distinguish among populations. At this time, one coded-wire tag indicator stock is used to represent the exploitation rate on all populations within a management unit. A more detailed description of the FRAM is provided below in C4.

Chinook Salmon

Alternative 1

To simplify the analysis, and yet give a current perspective on the outcome of fisheries, modeling chinook salmon catch and escapement for the four alternative fishing regimes was based on the forecasts of abundance developed for pre-season planning in 2003. Modeling of Alternative 1 was based on the 2003 pre-season FRAM run, with some adjustments in the harvest objectives (e.g., Exploitation Rate [ER] ceilings) for some management units to reflect the ~~proposed 2004–2009~~ Puget Sound Chinook Harvest Management Plan (HMP) proposed for implementation during the 2005–2009 fishing seasons, and consequent shaping of fisheries to achieve all those objectives. The pre-season (prior to implementation of the fisheries) expectations in 2003 were used to assess Alternative 1 because: 1) 2003 is generally representative of status quo conditions – management objectives were identical to the proposed Puget Sound chinook harvest plan; 2) it includes impacts to chinook that

occur in pink fisheries that do not occur in even-numbered years, and; 3) pre-season expectations better reflect the intended implementation of the HMP.

The pre-season 2003 fishing regime provides a valid general example of management intent under the HMP. Because chinook salmon from critical and non-critical units commingle in many marine areas, meeting the objectives for the weak stocks implies that otherwise-surplus chinook from strong units will not be harvested. In principle, this surplus could be harvested selectively in freshwater areas. However, the HMP states that stronger stocks will only be harvested ‘down’ to their escapement goals, or ‘up’ to their ER ceilings, if they meet stringent criteria defining harvestable surplus. It was assumed that these conditions would not be met during the term of the proposed HMP, so for many units (e.g., Skagit spring, Stillaguamish, Snohomish), the surplus was accrued to escapement. For other units (e.g., Green, Nisqually, Puyallup), harvestable surplus was forecasted, so the pre-season FRAM was configured to harvest that surplus, ‘up’ to the Recovery Exploitation Rate (RER), or ‘down’ to the stated escapement goal.

Chinook salmon escapement estimates for each Puget Sound management unit were taken from FRAM runs that simulated each scenario under Alternative 1. The FRAM subtracts fishery-related mortality that occurs through the month of September from the initial (i.e., unfished) abundance of each unit, then discounts the contribution of surviving 2-, 3-, and 4-year-old fish, according to their maturation rates.

Alternatives 2 and 3

Due to the implications of escapement goal management, Alternatives 2 and 3 involved similar, very sweeping changes in the distribution of fisheries, relative to Alternative 1. Under Alternative 3, terminal-area fisheries were defined as those harvesting only local-origin chinook. For example, the terminal area for the Skagit River would be defined where only Skagit-origin chinook would be caught. However, it was determined at the outset that virtually all marine area fisheries in Puget Sound encounter a mixture of Puget Sound chinook stocks. Since the abundance of one or more of these commingled stocks was below their escapement goals, marine area fishing was precluded under both Alternative 2 and 3. It was assumed that freshwater fishing areas harvested only the local management unit, and, in the case of the Skagit River where spring and summer/fall chinook units are present, they could be selectively harvested in management periods. In actuality, straying probably occurs naturally in all systems, so that even freshwater fisheries may encounter small numbers of non-local chinook. The fisheries regime developed to model Alternatives 2 and 3 allowed freshwater chinook fisheries to occur where abundance exceeded the escapement goals. Where chinook abundance was less than the

escapement goals, chinook fisheries, and fisheries directed at other salmon species that incur incidental chinook mortality, were precluded.

With commercial and recreational fishing limited to freshwater areas, the technical workgroup assessed the extent to which harvestable surplus could be caught. It was assumed that treaty commercial and recreational fisheries would operate at their current scale of effort (i.e., fleet sizes, recreational trips), use existing gear types and season structure, and occur only in rivers where such commercial or recreational fishing has occurred in recent years. For example, if a large harvestable surplus was forecast to occur for a given stock, a priori judgment determined whether the local tribal commercial fleet effort (operating within their defined ‘usual and accustomed area’) and recent freshwater recreational angling effort could reasonably catch the harvestable surplus. Based on past harvest rates and harvest rates in areas of similar fleet size and fishery structure, the workgroup concluded that the Green River fishery was capable of harvesting the full amount of chinook (11,500) above the escapement goal. In contrast, it was determined that the current fleet size and fishery structure in the Nooksack-Samish area would not be capable of harvesting the total surplus of fall chinook (41,900) above its hatchery escapement goal.

If the lack of harvestable surplus chinook precluded freshwater fisheries that would directly or incidentally harvest chinook, late-season chum and steelhead fisheries (i.e., those occurring from December through March) were assumed free of incidental impacts to listed chinook, and thus included in Alternative 2 and 3. The co-managers’ fish ticket database provided support for this assumption.

No new fisheries were envisioned for Alternative 2 or 3. For example, non-tribal commercial fisheries have not occurred in the Strait of Juan de Fuca (Marine Catch Areas 4B, 5, and 6C), deep South Puget Sound (Marine Catch Areas 13 through 13I), or freshwater areas for at least two decades, based on agreements with the tribes and to meet allocation objectives among non-tribal commercial and recreational users. It was assumed that the size of treaty gillnet fishing fleets that have operated recently in these freshwater areas would not expand. Fishing was not expanded to any freshwater areas that have not been recently opened to commercial or freshwater salmon harvest, even though, with the closure of marine areas, substantial harvestable surplus was projected to occur in some such areas. Similarly, it was assumed that recreational effort or regulatory bag limits would not increase, and the current scale of mark selective fisheries would not expand. These somewhat qualitative assessments of the harvest capability of existing commercial and recreational fisheries were made by a small group of WDFW and tribal fisheries management biologists.

With forecasts of which stocks would return with harvestable abundance, and having determined the potential for current fishing effort to harvest that surplus, harvest scalars or catch levels were input accordingly to the FRAM. The primary distinction between the structure of fisheries in Alternatives 2 and 3 was due to different escapement goals. When more than one population returns to a given river, for some management units Alternative 3 would set a more constraining escapement goal for the management units appropriate to its weakest population.

The principle difference between the chinook salmon harvest allowed under Alternatives 2 and 3, and consequently the difference in allowable harvest of other species, was due to the harvestable surplus of listed chinook in the Snohomish and Stillaguamish units associated with Alternative 2. The chinook surplus also enabled harvest of pink, coho, and chum salmon in the Stillaguamish River and in Tulalip Harbor (Area 8D). Area 8D is an isolated marine area, adjacent to the hatchery facilities of the Tulalip Tribes; harvest in that area is believed not to harvest non-local chinook.

Chinook escapement was estimated as the catch subtracted from the predicted abundance, i.e., those fish that escaped the fishery to spawn. It should be noted that the escapement does not increase by the same amount as the difference in catch between Alternatives 2 or 3 and Alternative 1. This is because escapement is comprised of those fish that escape fisheries to spawn. In the absence of fisheries, not all fish would escape. Some would die of natural causes, and some fish would remain in marine waters to mature and return to spawn in future years.

Alternative 4

Alternative 4 involves the closure of all fisheries that would harvest any listed Puget Sound chinook salmon, regardless of their forecast abundance status, precluding all marine area fisheries, and all freshwater fisheries except those late-season chum and steelhead fisheries (operating from December through March) that would have no incidental impact to chinook.

Abundance and Northern (Canadian/Alaskan) Fishery Scenarios

NMFS decided early in the DEIS analysis to examine the contingent effects of variable abundance, and increasing northern (Canadian/Alaskan) fishery interceptions, on harvest and escapement of Puget Sound chinook. As explained in DEIS Section 2, Alternatives Including the Proposed Action, the two abundance conditions modeled for Puget Sound chinook were the 2003 forecast level, and 30 percent reduced abundance (Table C3-1). The need to examine the effects of variable abundance was driven, in part, by the widely accepted view that marine survival has varied in a cyclic manner (Mantua et al. 1997), and evidence that freshwater survival has also varied widely under the primary influence of

incubation period flows (Seiler et al. 2002). The reduced abundance condition was based on observations of the period 1990 through 1999, for which average, aggregate abundance of all Puget Sound salmon stocks, natural and hatchery production combined, was approximately 30 percent lower than forecast for 2003. Individual natural and hatchery stocks varied independently to a greater or lesser extent

Table C3-1. Annual abundance of Puget Sound chinook salmon management units under 2003 forecasted and 30 percent reduced conditions, expressed as AEQ catch and escapement from the FRAM.

	2003	-30%

Puyallup	11548	8084
Nisqually	27040	18928
Hood Can	47542	33279
JDF	4234	2964

Chinook salmon abundance during the term of the proposed HMP cannot be forecasted exactly, and may in fact increase from the 2003 level. However, the average of the previous decade provides a reasonable view of the potential for abundance to decline.

It was necessary to examine the effects of higher northern (Canadian/Alaskan) fishery interceptions because the stated intent of the Canada Department of Fisheries and Oceans, and recent-year catch estimates support this likelihood. The modeled high northern fishery condition comprised different assumptions for the various areas. The west coast Vancouver Island troll fishery, and troll fisheries in Southeast Alaska were modeled at the maximum levels allowed by the current Chinook Annex to the Pacific Salmon Treaty (PST). Canadian fisheries in the Strait of Georgia and the Strait of Juan de Fuca were modeled as the observed catch in 1996 and 2002, respectively. Other northern fisheries were modeled at the level forecast for 2003.

Recreational Effort

To assess economic consequences, it was necessary to estimate recreational fishing effort for each alternative. To estimate the number of recreational trips corresponding to modeled harvest, catches of all salmon, whether caught in marine areas or freshwater, and including chinook and coho from FRAM runs, were multiplied by 4. This generic estimate of salmon ‘angler success’ (i.e., 0.25 fish per trip) was derived from the WDFW Catch Record Card Analysis used to estimate recreational catch and effort on an annual basis.

Other Salmon Species

Modeled catch only differed among alternatives, and was not specified differently for the abundance / northern (Canadian/Alaskan) fishery scenarios, which were intended to assess only the effect of variable chinook abundance and northern fisheries on chinook catch. The high and 2003 northern fishery conditions included in the scenarios may imply a different level of coho catch in Canada, and therefore affect coho catch in Puget Sound, but these indirect effects could not be reliably predicted.

Coho

Commercial and recreational coho salmon harvest was extracted directly from the final 2003 pre-season coho FRAM model for Alternative 1. For Alternatives 2 and 3, marine area fisheries were closed, and only those freshwater fisheries left open where harvestable chinook abundance also enabled coho harvest. These open fisheries corresponded to those in the chinook models created to simulate Alternatives 2 and 3. No coho fishing was allowed under Alternative 4.

Coho escapement estimates for each Puget Sound management unit extracted from FRAM 0319 (April 2003) for Alternative 1, and modified as necessary to simulate the freshwater fisheries associated with Alternatives 2, 3, and 4.

Sockeye

Sockeye salmon are primarily caught by commercial fisheries in marine fishing areas, in particular those fisheries directed at Fraser River (British Columbia) stocks that occur in the Strait of Juan de Fuca (SJDF) and San Juan Islands (SJI). However, in years when the Lake Washington sockeye run exceeds its escapement goal (325,000), commercial and recreational fisheries occur in the Lake Washington Ship Canal and Lake Washington, respectively. Relatively small tribal commercial fisheries, intended to harvest Lake Washington sockeye salmon, also occur in Central Puget Sound under this circumstance. The Baker River (Skagit system) sockeye salmon stock has occasionally

returned at levels slightly above the escapement goal, but the small surplus has been harvested in the river by tribes for ceremonial and subsistence purposes. This Baker River fishery was not included in any alternative model.

For Alternative 1, Fraser sockeye catch in the SJDF and SJI areas was modeled as the average of actual catch in 1998–2002. Lake Washington sockeye catch in marine and freshwater areas was modeled as the average of three recent years in which these fisheries occurred – 1996, 2000, and 2002. For Alternatives 2, 3 and 4, no sockeye catch was modeled, because the marine areas were closed due to commingled weak chinook stocks, and the terminal (freshwater) areas were closed because the forecast abundance of Lake Washington (Cedar River) chinook was below the escapement goal.

Pink

Pink salmon harvest occurs primarily in odd-numbered years in Puget Sound, due to the predominance of odd-year returning stocks in Puget Sound and southern British Columbia. The majority of pink salmon harvest occurs in treaty and non-Indian commercial fisheries directed at Fraser River stocks that occur in the SJDF and SJI in August and September. For Alternative 1, pink harvest in these marine areas was modeled as the average of the last three fisheries (i.e., 1997, 1999, and 2001).

A subset of pink salmon stocks in Puget Sound systems has consistently reached harvestable abundance, so models of Alternatives 1, 2, and 3 included terminal-area marine and/or freshwater, commercial and recreational fisheries to harvest that surplus. These abundant stocks include those in the Skagit, Stillaguamish, Snohomish, and Puyallup Rivers. These fisheries were modeled for Alternative 1 as they were projected during 2001 pre-season planning from forecast abundance.

Pink salmon stocks in Puget Sound are managed to achieve escapement goals. Harvestable surplus is projected to occur, during pre-season planning, based on the surplus in excess of escapement goals, allocated to treaty and non-Indian fisheries.

Chum

Commercial fisheries directed at fall chum salmon occur throughout Puget Sound in marine and freshwater areas. Harvestable surplus was modeled for Alternative 1 according to 2001 forecast abundance in excess of escapement goals. Fall chum fisheries generally extend from the last week of October through mid-December in freshwater areas, so harvest in December comprises a small proportion of the total harvestable abundance. Recreational chum salmon catch in marine and freshwater areas was modeled as the 1997–1999 average, from Catch Record Card estimates. For

Alternatives 2 and 3, chum salmon harvest was precluded in some rivers due to the lack of surplus chinook that would be caught incidentally, except in the late season (December) when chinook are absent. The late chum stock that returns to the Nisqually River supports commercial and recreational fisheries that extend from December through January, so it is the only salmon population that would be harvested as usual under Alternative 4.

For Alternatives 2 and 3, chum salmon fisheries in freshwater were modeled to harvest surplus chum, subject to the availability of surplus chinook that would be caught incidentally.

Steelhead

Small-scale commercial fisheries for winter steelhead are promulgated by the tribes in many freshwater areas, and usually extend from December through April. Recreational steelhead fisheries are not included in the Proposed Action. Commercial steelhead catch was modeled according to pre-season forecasts (Status Reports) in some areas, and from recent-year average catch in other areas. Summer steelhead fisheries, defined for the purpose of this modeling exercise as those occurring from June through November, were included in the model for Alternative 1, but not in models for Alternatives 2, 3, or 4.

Appendix C – Technical Methods – Derivation of Harvest Management Standards and Fishery Impacts

Note: It is suggested that these tables be printed on larger paper to improve readability.

Appendix C4. Structure and Function of the FRAM

The Fishery Regulation Assessment Model (FRAM) is currently used by the Pacific Fishery Management Council (PFMC) to annually estimate impacts of proposed ocean and terminal fisheries on chinook and coho salmon stocks. The DEIS incorporates by reference a document entitled “FRAM – An overview for chinook and coho”, written by the Model Evaluation Workgroup for the Salmon Technical Team of the PFMC¹. The following was excerpted from that report.

FRAM is a single season modeling tool with separate processing code for chinook and coho salmon. The chinook version evaluates impacts on most stock groups originating from the south central Oregon coast, Columbia River, Puget Sound, and Southern British Columbia. The coho version evaluates impacts on a comprehensive set of stocks originating from Central California to Southeast Alaska and represents total West Coast production. The FRAM produces a variety of output reports that are used to examine fishery impacts for compliance with management objectives, allocation arrangements, ESA compliance, and domestic and international legal obligations. Until recently FRAM was not used for assessing compliance with chinook or coho agreements in international fisheries management forums. However, the U.S. and Canada have agreed to develop a bilateral regional coho planning tool. FRAM will be used for the development of the first version of this regional model. The intent is to have a single common tool that can support both domestic and international fishery planning processes using a common set of data and assumptions.

BACKGROUND

The need for salmon fishery assessment tools at the stock-specific level became apparent beginning in the mid-1970s with treaty fishery rights litigation and the associated legal obligation for the states of Washington and Oregon to provide treaty tribes with the opportunity to harvest specific shares of individual runs. Other legal issues such as the Magnuson Fishery Conservation Management Act and the Law of the Seas convention contributed to the need for developing better assessment tools. These legal issues in conjunction with the information available from the coast wide coded wire tag (CWT) program provided the impetus for developing the early salmon fishery assessment models.

In the late 1970s, the Washington Department of Fisheries (WDF) and U.S. National Bureau of Standards (NBS) developed a model for evaluating alternative fishery regulatory packages. The WDF/NBS Model could be configured for either chinook or coho by using different input data files. This model was coded in FORTRAN and ran on a mainframe computer at the University of Washington. Model runs were usually processed over night and results were painstakingly extracted from large volumes of printed output reports. The WDF/NBS model was not extensively used by the PFMC because it proved costly to operate and its results were difficult to obtain in a timely manner. Morishima and Henry (2000) provide a more in-depth history of Pacific Northwest salmon management and fishery modeling.

In the early 1980s, the development of personal computers permitted the WDF/NBS model to be converted into simple spreadsheet models. This transformation improved accessibility to the

¹ Yuen, H., A.Rankis., L.LaVoy, J.Packer, C.Melcher, R. Conrad , C. D. Simmons, R. Sharma, and A.Grover. 2004 In prep. FRAM: an overview of chinook and coho. Report of the Model Evaluation Workgroup to the STT.

model during the PFMC preseason planning processes. The first spreadsheet model for chinook used by the PFMC was developed in the mid 1980s to model Columbia River “tule” fall chinook. The Coho Assessment Model (CAM) was the corresponding spreadsheet model for coho and covered stocks from the Columbia River, Puget Sound, and Washington and Oregon coastal areas. The Coho Assessment Model was revised over time, principally to improve report generation capabilities and provide more detailed information on management of terminal area fisheries through the use of Terminal Area Management Modules (TAMMs). The CAM was used as the primary model for evaluating coho impacts for PFMC fisheries until the mid 1990s.

Increasing demands for information soon outstripped the capacity of these spreadsheet models to evaluate the fishery regimes under consideration by the PFMC. In the mid 1990s, CAM was programmed in QUICK BASIC and was renamed FRAM. The recognition that common algorithms underlie both the coho and chinook spreadsheet models led to the effort to develop the QUICK BASIC version of FRAM for both species. The FRAM code could be used to evaluate fishery regimes for either chinook or coho by using different input file configurations. In 1998, FRAM was converted to VISUAL BASIC to take advantage of improved user interfaces available through the MS WINDOWS operating system. A multi-agency Model Evaluation Subgroup periodically reviewed model performance and parameter estimation methods and coordinated revisions to model capabilities during this period (1998-2000).

MODEL OVERVIEW

The FRAM is a discrete, time-oriented, age-structured, deterministic computer model intended to predict the impacts from a variety of proposed fishery regulation mechanisms for a single management year. It produces point estimates of fishery impacts by stock for specific time periods and age classes. The FRAM performs bookkeeping functions to track the progress of individual stock groups as the fisheries in each time step exploit them. Individual stock age groups are exploited as a single pool, that is, in each time step all pre-terminal fisheries operate on the entire cohort and all terminal fisheries operate on the mature run.

Currently, 33 stock groups are represented in Chinook FRAM and 128 stock groups are represented in Coho FRAM (see Appendices 1 and 2 for lists of the stocks). Each of these groups have both marked and unmarked components to permit assessment of mark-selective fishery regulations. For most wild stocks and hatchery stocks without marking or tagging programs, the cohort size of the marked component is zero and therefore the current version of FRAM has a virtual total of 66 stock groups for chinook and 256 for coho. Stocks or stock-aggregates represented in the FRAM were chosen based on the level of management interest, their contribution rate to PFMC fisheries, and the availability of representative CWT recoveries in the fisheries.

The FRAM includes pre-terminal and terminal fisheries in southeast Alaska, Canada, Puget Sound, and off the coasts of Washington, Oregon, and California. There are 73 fisheries in Chinook FRAM and 206 fisheries in Coho FRAM. The intent is to encompass all fishery impacts to modeled chinook and coho stocks in order to account for all fishing-related impacts and thereby improve model accuracy. Terminal fisheries in Chinook FRAM are aggregations of gears and management areas. Terminal fisheries in Coho FRAM are modeled with finer resolution, most notably by including individual freshwater fisheries. Fishery number and fishery name for each of the FRAM fisheries are listed in Appendix 3 for chinook and Appendix 4 for coho.

The time step structure used in FRAM represents a compromise level of resolution that corresponds to management planning fishery seasons and species-specific migration and maturation schedules.

The FRAM consists of four time periods for chinook and five periods for coho (Table 2-1). At each time step a cohort is subjected to natural mortality, pre-terminal fisheries, and also potentially to maturation (chinook only), and terminal fisheries.

Table 2-1. FRAM time steps for coho and chinook.

Period	Coho Months	Period	Chinook Months
Time 1	January-June	Time 1	Preceding October-
Time 2	July	Time 2	May-June
Time 3	August	Time 3	July-September
Time 4	September	Time 4	October-April
Time 5	October -		

The recovery data available in the CWT database limit the time-step resolution of the model. Increasing the time-step resolution of the model usually decreases the number of CWT recoveries for a stock within a time period. Since estimation of fishery impacts, like exploitation rates, is dependent on CWT recovery information, decreasing the number of CWT recoveries in time/area strata increases the variance of the estimated exploitation rates in those strata. In recognition of these data limitations, efforts were made to restrict the level of time-step resolution to that necessary for fishery management purposes.

Major assumptions and limitations of the model are described briefly below.

1. CWT fish accurately represent the modeled stock. Many “model” stocks are aggregates of stocks that are represented by CWTs from only one component. For example, in many cases wild stocks are aggregated with hatchery stocks and both are represented by the hatchery stock’s CWT data. Therefore, for each modeled stock aggregate, it is assumed that the CWT data accurately depict the exploitation and distribution of the untagged fish in the modeled stock.
2. Length at age of chinook is stock specific and is constant from year to year. Growth functions are used for chinook in determining the proportion of the age class that is legal size in size-limit fisheries. Parameters for the growth curves were estimated from data collected over a number of years. It is assumed that growth in the year to be modeled is similar to that in the years used to estimate the parameters.
3. Stock distribution and migration is constant from year to year and estimated as the average distribution in the base period data. We currently lack data on the annual variability in distribution and migration patterns of chinook and coho salmon stocks. In the absence of such estimates, fishery-specific exploitation rates are computed relative to the entire cohort. Changes in the distribution and migration of stocks from the base period will result in poor estimates of stock composition and stock-specific exploitation rates.
4. There are not multiple encounters with the gear by the fish in a specific time-area fishery stratum. Within each time-area fishery stratum, fish are assumed to be vulnerable to the gear only once. The catch equations used in the model are discrete and not instantaneous. Potential bias in the estimates may increase with large selective fisheries or longer time intervals, both of which increase the likelihood that fish will encounter the gear more than once.

While it is difficult to directly test the validity of these assumptions, results of validation exercises could provide one assessment of how well these assumptions are met and the sensitivity of the model to the assumptions. Currently, there is little effort directed at model validation.

BASE PERIOD DATA

The Chinook FRAM is calibrated using escapement, catch, and CWT recovery data from 1974-1979 brood year CWT releases. During the late 1970s and early 1980s, fisheries were being conducted across an extensive geographic area and over an extended period of time, thus giving the best available representation of CWT stock distribution. Not all stocks represented in the Chinook FRAM have CWT recovery data available from the 1974-1979 brood year base period (e.g., Snake River fall chinook). These stocks are categorized as “Out-of-Base” stocks. Available CWT data for these stocks are translated to equivalent base period recovery and escapement data using known fishing effort and harvest relationships between recovery years.

Model base period data for the Coho FRAM is derived from fishery and escapement recoveries of CWTs and terminal area run size estimates for the return years 1986-1991.

Chinook and coho base period data are used to estimate base period stock abundances and age-specific time-area fishery exploitation rates and maturation rates for modeled stocks. These estimates are derived through species-specific cohort analysis procedures. Cohort analysis is a series of steps and processes that uses CWT recoveries and base period catch and escapement data to “back-calculate” or reconstruct a pre-fishing cohort size for each stock and age group using assumed natural mortality and incidental mortality rates.

GENERAL INPUT TYPES

The five general types of input values used by FRAM are:

1. Cohort Abundance: For each stock or stock aggregate, an annual estimate of abundance is obtained from a source that is independent of the model. For preseason simulation modeling, these forecasts of stock abundance are used to estimate initial cohort size. For chinook, initial stock abundance estimates are segregated by age class, from age-2 to age-5 year old fish. For coho, only one age class (age 3) is assumed vulnerable to fisheries. Coho abundances are input to the model as January age-3 abundance. Chinook and coho abundance estimates are further segregated by mark status (“marked” or “unmarked”).
2. Size Limits: For chinook, minimum size limits are specified by fishery where appropriate. For coho, age-3 fish are assumed fully vulnerable and age-2 fish are assumed fully invulnerable to modeled fisheries.
3. Fishery Catch Mortality: The model provides five options for estimating mortality in a fishery: a quota, an exploitation rate scalar, a ceiling, “selective”, and harvest rate (for Puget Sound terminal fisheries only).
 - a) Quota. Catch in the fishery is set equal to a value input by the user.
 - b) Exploitation rate scalar. The exploitation rate in the fishery is scaled, relative to the base period, using a scalar input by the user.
 - c) Ceiling. Catch is first calculated based on an exploitation rate scalar and then compared to a ceiling; if the estimated catch exceeds the ceiling, then the catch is truncated at the ceiling value.
 - d) Selective. Identified as either a quota or exploitation rate scalar controlled fishery with additional calculations to cover catches and encounters for marked and unmarked groups.

- e) Harvest rate. A terminal area harvest rate is applied to either all fish present in the terminal area or to the number of local-origin stock only.
4. **Release Mortality:** This is the mortality associated with the release of landed fish from hook-and-line and other gears. Release mortality rates assumed for coho are shown in Table 3-1a and for chinook in Table 3-1b. Hook-and-release mortality is assessed when coho or chinook are not allowed to be retained (so-called “chinook/coho non-retention”, or CNR fisheries), when size limits apply, or in mark-selective fisheries. Release mortality has been estimated in a number of studies of hook-and-line fisheries, and release mortality rates for troll and recreational fisheries in the ocean have been formally adopted by the PFMC. Release mortality in net fisheries for chinook or coho non-retention is estimated external to FRAM and input into the model as either “landed catch” or as CNR mortality.
- Mark-selective fisheries have two additional variations of “release” mortality that are described as either the inappropriate retention of an unmarked fish or the release of a marked fish which consequently endures some release mortality. The failure to release an unmarked fish is a user input to the model called “Unmarked Recognition Error” (or Retention Error Rate) and is the proportion of the unmarked fish encountered that are retained. The release of marked fish that subsequently die due to release is a user input to the model called “Marked Recognition Error” and is the proportion of the marked fish encountered that are released. These rates are identified in Table 3-2.
5. **Other Non-landed Mortality:** This category includes fishing-induced mortality not associated with direct handling (or landing) of the fish (see Table 3-1a for coho and Table 3-1b for chinook). Application is for sport and troll hook-and-line “drop-off” (fish that drop off from the hook before they are brought to vessel but die from hook injuries), and net gear “drop-out” (fish which are not brought on board but die from injury as a result of being netted). In general, a 5% mortality rate is applied to the landed catch to account for “other non-landed mortality” in hook-and-line fisheries. Net drop-out mortality rates vary depending on species, net type, or terminal versus pre-terminal nature of the fishery.

Table 3-1a. FRAM/TAMM fishery-related mortality rates for coho salmon used for Southern U.S. fisheries in 2003.

Fishery: designated by area, user group, and/or gear type	Fishery Type	Comments	Release Mortality	"Other" Mortality^a

OUTPUT REPORTS AND MODEL USE

Model results are available as either standard FRAM printed output reports or in Excel spreadsheets that are linked to FRAM results/reports. The TAMM spreadsheets provide comprehensive summaries of fishery mortality, exploitation rate, run size, and escapement for key stocks in the PFM and North of Falcon annual salmon season setting processes. Early versions of these spreadsheets focused on finer resolution of stocks and fisheries for Puget Sound terminal areas. The TAMM spreadsheets have now broadened in scope and contain information for both pre-terminal and terminal fisheries as well as FRAM fishery inputs for terminal fisheries in coastal Washington (coho) and in Puget Sound (both species). Other model results not shown in the spreadsheets can be generated directly from FRAM. These reports include summaries of catch by fishery, catch by stock, catch by age, and escapement/run size reports. A new report has been created for FRAM to provide more detailed information relative to mark-selective fisheries for chinook and coho. For a full scope of FRAM report generating functions, refer to “Users Manual for the Fishery Regulation Assessment Models (FRAM) for Chinook and Coho” (MEW *in prep.*).

COMPUTATIONAL STRUCTURE

For each time step and fishery, FRAM simulates fishery regulations following the sequence of computations depicted for coho (Figure 1) and chinook (Figure 2). The first step for both coho and chinook is to scale the predicted cohort size for the current year to the base period: this is done by stock for the January age-3 cohort for coho and for the age-2 through age-5 cohorts for chinook. Each stock's cohort is then processed through a time step loop defined for the species (five time steps for coho and four for chinook). Within the time step loop: (1) natural mortality is applied to the beginning cohort size; (2) the procedures to calculate projected catches for the all fisheries in the time step are executed; and (3) all fishery mortalities for the cohort (stock) are totaled and the remaining abundance of the stock is calculated.

Figure 1. Flow chart for FRAM coho model.

Figure 2. Flow chart for FRAM chinook model.

After FRAM has processed all steps in the time step loop, the program checks for the presence of an optional Terminal Area Management Module (TAMM). If the model user has not specified a TAMM input file for additional modeling, FRAM processing is complete and final terminal run sizes (chinook) or escapements (coho) are calculated. If a TAMM has been specified, then FRAM will repeat processing through the specified fisheries and time step loops. Although TAMMs are focused upon terminal area fisheries, some of these fisheries are in mixed-stock areas and may also impact both mature and immature chinook. Thus there exists an iterative FRAM/TAMM process to obtain the final tabulations of fishery mortalities and stock escapements (see Section 7 for further TAMM explanation).

Scale Cohort to Base Period

The equation below establishes the starting cohort size for all stocks as a product of two parameters: the average cohort size for stock s at age a ($BPCohort_{s,a}$) during the base period and a stock and age specific scalar ($StockScalar_{s,a}$). $StockScalar_{s,a}$ is estimated externally to the model and is an annual input to the model.

$$Cohort_{s,a,1} = BPCohort_{s,a} \times StockScalar_{s,a}$$

Natural Mortality

At the beginning of each time step, each cohort is decreased to account for projected natural mortality using the following equation:

$$Cohort_{s,a,t} = Cohort_{s,a,t-1} \times (1 - M_{a,t})$$

where $M_{a,t}$ is the natural mortality rate for age a fish during time step t (see Appendix Table 5 for specific rates used for coho and chinook).

Catch

The FRAM simulates fisheries through the use of linear equations. Different types of computations are used depending upon whether or not a fishery operates under mark-retention restrictions. If all fish can be retained regardless of mark status, the following general formula is used (mark-selective fisheries are described in Section 6.5):

$$Catch_{s,a,f,t} = BPER_{s,a,f,t} \times Cohort_{s,a,t} \times PV_{s,a,t} \times FishScalar_{f,t} \times SHRS_{s,f,t}$$

where:

$Catch_{s,a,f,t}$	=	Catch of stock s , age a , in fishery f , at time step t ;
$BPER_{s,a,f,t}$	=	Base Period Exploitation Rate (harvest rate for terminal fisheries) for stock s , age a , in fishery f , at time step t ($BPER$ is derived from cohort analysis using CWT release and recovery data);
$Cohort_{s,a,t}$	=	Number of fish in cohort (chinook are expressed as both immature and mature cohorts) for stock s at age a in time step t ;
$PV_{s,a,t}$	=	Proportion of cohort for stock s , age a , vulnerable to the gear at time step t (for chinook PV is a function of a Von Bertalanffy growth curve; for coho PV is always = 1.0);
$FishScalar_{f,t}$	=	Impact scalar for fishery f at time step t relative to the base period; and
$SHRS_{s,f,t}$	=	Stock-specific exploitation rate scalar for stock s , in fishery f , at time step t (the default value of 1.0 is rarely changed).

The parameter $FishScalar_{f,t}$ is the foundation for the model's fishery simulation algorithms. FRAM can evaluate two general types of fisheries: (1) effort-based or (2) catch-based. For effort-based fisheries, the parameter $FishScalar_{f,t}$ is specified by the modeler to reflect expected effort relative to the average effort observed during the model's base period. For catch-based fisheries, $FishScalar_{f,t}$ is computed automatically so as to attain a specified catch level. If the catch level is to be modeled as a quota, then $FishScalar_{f,t}$ is computed as:

$$FishScalar_{f,t} = \frac{QuotaLevel_{f,t}}{\sum_s \sum_a Catch_{s,a,f,t} \times (1 / PropModelStock_f)}$$

where $\sum_s \sum_a Catch_{s,a,f,t}$ is computed with $FishScalar_{f,t} = 1.0$ and $PropModelStock_f$ is the proportion of model stocks in the catch to the total catch in fishery f for the base period ($PropModelStock_f$ is used for chinook only, it is always set to 1.0 for coho).

If the catch level is to be modeled as a ceiling, both an effort scalar and quota are specified. A catch estimate is made during a first iteration of FRAM using the effort scalar. If the effort scalar computes a catch level that is less than the catch ceiling, then the final catch estimate is this effort-based catch. If the initial effort scalar computes to a catch level that exceeds the ceiling, then the final catch estimate is the quota. In the case of a ceiling-type fishery, the final $FishScalar_{f,t}$ will be calculated based on the lower of the two types of catch estimates (effort scalar or quota).

Incidental Mortality

Several types of incidental mortality can be accounted for in FRAM either through external calculations of mortality or internal FRAM processing. Incidental mortality associated with hook-and-line drop-off and net drop-out is expressed as a fraction of retained catch or as a fraction of encounters in the case of mark-selective fisheries. Incidental mortality in mark-selective fisheries is discussed in the next section.

Mortalities in species non-retention fisheries (CNR) are derived using four different methods for chinook and one for coho. Chinook non-retention mortalities are model estimates from inputs of: the level of open versus non-retention effort within each time step (Methods 1 and 2), legal and sub-legal encounters (Method 3), or from total encounters (Method 4). The method for coho is simply an external-to-the-model estimate of coho mortalities in a fishery based on historical observations. The methods were developed to fit the observations from various fisheries. Method 1 was developed for Canadian and Alaskan fisheries that had both open and non-retention regulation periods and had changes in the gear or fishing patterns to avoid chinook encounters.

METHOD 1 – Computed Mortalities

$$CNRLegal_{s,a,f,t} = Catch_{s,a,f,t} \times \frac{1 - FishScaler_{f,t}}{FishScaler_{f,t}} \times RelRate_{f,t} \times LegalSelRate_{f,t}$$

$$TotalLegPop_{f,t} = \sum_s \sum_a (Cohort_{s,a,t} \times PV_{s,a,t}) \text{ for stocks with catch in fishery } f$$

$$TotalSubLegPop_{f,t} = \sum_s \sum_a (Cohort_{s,a,t} \times (1 - PV_{s,a,t})) \text{ for stocks with catch in fishery } f$$

$$EncRate_{f,t} = TotalSubLegPop_{f,t} / TotalLegPop_{f,t}$$

$$TotCatch_{f,t} = \sum_s \sum_a Catch_{s,a,f,t} \times (1 / PropModelStock_f)$$

$$CNRSub_{s,a,f,t} = TotCatch_{f,t} \times EncRate_{f,t} \times \frac{1 - FishScaler_{f,t}}{FishScaler_{f,t}} \times RelRate_{f,t} \times SubSelRate_{f,t} \times PropSubPop_{s,a,f,t}$$

METHOD 2 – Ratio of Non-Retention to Retention Days

$$CNRLegal_{s,a,f,t} = Catch_{s,a,f,t} \times (CNRDays_{f,t} / RetentDays_{f,t}) \times RelRate_{f,t} \times LegalSelRate_{f,t}$$

$$CNRSub_{s,a,f,t} = Shakers_{s,a,f,t} \times (CNRDays_{f,t} / RetentDays_{f,t}) \times SubSelRate_{f,t}$$

METHOD 3 – External Estimates of Legal and Sub-Legal Sized Encounters

$$LegalPropCatch_{s,a,f,t} = Catch_{s,a,f,t} / TotCatch_{f,t}$$

$$SubLegPop_{s,a,t} = Cohort_{s,a,t} \times (1 - PV_{s,a,t})$$

$$SubLegNR_{s,a,f,t} = SubLegPop_{s,a,t} \times SubER_{s,a,f,t} \times RelRate_{f,t}$$

$$SubLegPropEnc_{s,a,f,t} = SubLegNR_{s,a,f,t} / \sum_s \sum_a SubLegNR_{s,a,f,t}$$

$$CNRLegal_{s,a,f,t} = LegalPropCatch_{s,a,f,t} \times LegalEnc_{f,t} \times RelRate_{f,t} \times PropModelStock_f$$

$$CNRSub_{s,a,f,t} = SubLegPropEnc_{s,a,f,t} \times SubLegEnc_{f,t} \times RelRate_{f,t} \times PropModelStock_f$$

METHOD 4 – External Estimate of Total Encounters

$$LegalPropCatch_{s,a,f,t} = Catch_{s,a,f,t} / TotCatch_{f,t}$$

$$LegalEnc_{s,a,f,t} = BPER_{s,a,f,t} \times Cohort_{s,a,t} \times PV_{s,a,t} \times SHRS_{s,f,t} \times LegalPropCatch_{s,a,f,t}$$

$$SubLegEnc_{s,a,f,t} = SubER_{s,a,f,t} \times SubLegPop_{s,a,t}$$

$$CNRScaler_{f,t} = \frac{TotalEstCNR_{f,t}}{\sum_s \sum_a LegalEnc_{s,a,f,t} + \sum_s \sum_a SubLegEnc_{s,a,f,t}}$$

$$CNRLegal_{s,a,f,t} = LegalEnc_{s,a,f,t} \times CNRScaler_{f,t} \times RelRate_{f,t}$$

$$CNRSub_{s,a,f,t} = SubLegEnc_{s,a,f,t} \times CNRScaler_{f,t} \times RelRate_{f,t}$$

METHOD 5 – Coho Non-Retention Mortalities from External Estimates

$$PropCatch_{s,f,t} = \frac{BPER_{s,f,t} \times Cohort_{s,t} \times SHRS_{s,f,t}}{\sum_s BPER_{s,f,t} \times Cohort_{s,t} \times SHRS_{s,f,t}}$$

$$CNR_{s,f,t} = EstCNRMorts_{f,t} \times PropCatch_{s,f,t}$$

where $Cohort_{s,a,t}$, $Catch_{s,a,f,t}$, $FishScaler_{f,t}$, $PV_{s,a,t}$, $PropModelStock_j$, $BPER_{s,a,f,t}$, and $SHRS_{s,f,t}$, are previously defined and:

$CNRLegal_{s,a,f,t}$	=	Legal-sized adult non-retention mortality for stock s , age a , in fishery f , at time step t ;
$RelRate_{f,t}$	=	Release mortality rate for fish in fishery f at time step t ;
$LegalSelRate_{f,t}$	=	Legal-sized adult selectivity rate for fishery f in time step t , in response to changes in gear or fishing pattern (model input for Methods 1 and 2);
$TotalLegPop_{f,t}$	=	Total number of legal-sized fish from modeled stocks available to fishery f at time step t ;
$TotalSubLegPop_{f,t}$	=	Total number of sub-legal sized fish from modeled stocks available to fishery f at time step t ;
$EncRate_{f,t}$	=	For modeled stocks, the ratio of sub-legal sized chinook encountered for every legal-sized chinook in fishery f at time step t ;
$TotCatch_{f,t}$	=	Total landed catch in fishery f at time step t ;
$CNRSub_{s,a,f,t}$	=	Sub-legal sized non-retention mortality for stock s , age a , in fishery f , at time step t ;
$SubSelRate_{f,t}$	=	Sub-legal sized selectivity rate for fishery f in time step t , in response to changes in gear or fishing pattern (model input for Methods 1 and 2);
$PropSubPop_{s,a,f,t}$	=	Proportion of sub-legal sized population for stock s , age a , in fishery f , at time step t ;
$CNRDays_{f,t}$	=	Number of non-retention days in fishery f , at time step t (model input for Method 2);
$RetentDays_{f,t}$	=	Number of retention days in fishery f at time step t (model input for Method 2);

$Shakers_{s,a,f,t}$	=	Sub-legal shaker mortality for stock s , age a , in fishery f , at time step t (see following sub-section for method of calculation);
$LegalPropCatch_{s,a,f,t}$	=	Proportion of legal-sized catch for stock s , age a , in fishery f , at time step t ;
$SubLegPop_{s,a,t}$	=	Sub-legal sized population for stock s , age a , at time step t ;
$SubLegNR_{s,a,f,t}$	=	Sub-legal sized non-retention mortalities for stock s , age a , in fishery f , at time step t ;
$SubER_{s,a,f,t}$	=	Sub-legal sized encounter rate for stock s , age a , in fishery f , at time step t calculated from base period data;
$SubLegPropEnc_{s,a,f,t}$	=	Sub-legal sized proportion of encounters for stock s , age a , in fishery f , at time step t ;
$LegalEnc_{f,t}$	=	Total number of legal-sized encounters in fishery f at time step t (model input for Method 3);
$SubLegEnc_{f,t}$	=	Total number of sub-legal sized encounters in fishery f at time step t (model input for Method 3);
$LegalEnc_{s,a,f,t}$	=	Legal-sized encounters for stock s , age a , in fishery f , at time step t ;
$SubLegEnc_{s,a,f,t}$	=	Sub-legal sized encounters for stock s , age a , in fishery f , at time step t ;
$CNRScalar_{f,t}$	=	Non-retention scalar in fishery f at time step t ;
$TotalEstCNR_{f,t}$	=	Total estimated non-retention (legal and sub-legal) in fishery f at time step t (model input for Method 4);
$PropCatch_{s,f,t}$	=	Proportion of coho catch for stock s in fishery f at time step t ;
$EstCNRMorts_{f,t}$	=	Estimated coho non-retention mortalities in fishery f at time step t (model input for Method 5); and
$CNR_{s,f,t}$	=	Coho non-retention mortality for stock s in fishery f , at time step t .

Sub-legal shaker mortality is not estimated for coho since most minimum size limits - if they exist - apply to age 2 fish that are not represented in the model. The sub-legal and legal size encounters are stock and age specific and are calculated using Von Bertalanffy growth curves generated from CWT data. The calculations for sub-legal sized chinook (shakers) are shown below:

$$SubLegProp_{s,a,t} = 1 - PV_{s,a,t}$$

$$SubLegPop_{s,a,t} = Cohort_{s,a,t} \times SubLegProp_{s,a,t}$$

$$Shakers_{s,a,f,t} = SubER_{s,a,f,t} \times SubLegPop_{s,a,t} \times FishScalar_{f,t} \times RelRate_{f,t}$$

where all components are defined previously and $(1 - PV_{s,a,t})$ is the proportion of the cohort for stock s , age a , vulnerable to the gear at time step t (for chinook PV is function of Von Bertalanffy growth curve; for coho PV is always = 1).

Mark-Selective Fisheries

The implementation of mark-selective fishery regulations requires the use of more complex computations. Different equations are employed for marked and unmarked fish. The time-period specific forms of the equations utilized in Coho FRAM under non-selective and mark-selective fisheries are depicted in the following table. Computations for chinook mark-selective fisheries must account for sub-legal mortality, which does not differ between marked and unmarked components. The counterpart equations for chinook would contain the elements associated with sub-legal mortality, but due to the increased complexity this introduces the analogous equations for chinook are not presented here.

Non-Selective Fisheries		Mark-Selective Fisheries	
	Discrete Equations	Marked Fish	Unmarked Fish
Landed mortalities	$C_{s,f} = ER_{s,f} \times N_{s,t}$	$C_{s,f} = ER_{s,f} \times N_{s,t} \times (1 - mre_f)$	$C_{s,f} = ER_{s,f} \times N_{s,t} \times ure_f$
Release mortalities		$R_{s,f} = ER_{s,f} \times N_{s,t} \times mre_f \times rm_f$	$R_{s,f} = ER_{s,f} \times N_{s,t} \times (1 - ure_f) \times rm_f$
Drop-off mortalities	$D_{s,f} = C_{s,f} \times dmr_f$	$D_{s,f} = ER_{s,f} \times N_{s,t} \times dmr_f$	$D_{s,f} = ER_{s,f} \times N_{s,t} \times dmr_f$

where:

- $C_{s,f}$ = number of landed mortalities of stock s in fishery f ;
- $D_{s,f}$ = drop-off mortalities for stock s in fishery f ;
- dmr_f = drop-off mortality rate in fishery f ;
- $ER_{s,f}$ = exploitation rate for stock s in fishery f (this parameter is equivalent to $BPER \times PV \times SHRS$ in the previously described formulation);
- mre_f = marked-retention error (releasing marked fish in a selective fishery) in fishery f ;
- $N_{s,t}$ = cohort size for stock s at the beginning of time period t ;
- $R_{s,f}$ = number of release mortalities for stock s in fishery f ;
- rm_f = release mortality rate in fishery f ; and
- ure_f = unmarked recognition error (retaining and landing unmarked fish in a selective fishery) in fishery f .

Maturation (chinook only)

For chinook, the maturation process occurs after the pre-terminal catch has been calculated and results in a mature cohort for each stock, age, and time step. The number of fish from the age a cohort for stock s that matures at time step t ($TermCohort_{s,a,t}$) is calculated by:

$$TermCohort_{s,a,t} = Cohort_{s,a,t} \times MatRate_{s,a,t}$$

where $MatRate_{s,a,t}$ is a stock, age, and time step specific maturation rate that is calculated from base period data. The mature portion of the cohort is available to those fisheries, during the same time period, that have been designated as harvesting only mature fish while the immature portion of the cohort ($Cohort_{s,a,t} - TermCohort_{s,a,t}$) is then used to initiate the next time step.

Escapement

All chinook fisheries in FRAM are designated as pre-terminal or terminal in the base period data. The terminal fisheries only harvest fish from the mature cohort thus simulating a migration pattern from the pre-terminal mixed stock areas. Escapement is defined as any fish from the mature cohort that does not die from fishery-related mortality. For coho, fisheries during time steps 1 through 4 are on immature fish and by default all coho fisheries in time step five are on mature fish. In the current versions of the chinook and coho base periods, all maturation and escapement of a stock occurs within a single time step. The only exceptions are Skagit stocks of spring and summer/fall chinook and Columbia River summer chinook. The equations for chinook and coho are given below:

chinook:

$$TotTermMort_{s,a,t} = \sum_{f=term} (Catch_{s,a,f,t} + Shakers_{s,a,f,t} + Dropoff_{s,a,f,t} + LegalShakers_{s,a,f,t} + CNR_{s,a,f,t})$$

$$Escape_{s,a,t} = TermCohort_{s,a,t} - TotTermMort_{s,a,t}$$

coho:

$$Escape_{s,a} = Cohort_{s,a,5} - (\sum_f (Catch_{s,f,5} + LegalShakers_{s,f,5} + Dropoff_{s,f,5} + CNR_{s,f,5}))$$

where (age = 3 and time step = 5 for coho):

$TotTermMort_{s,a,t}$	=	Total terminal fishery mortality for stock s , age a , at time step t ;
$Escape_{s,a,t}$	=	Escapement for stock s , age a , at time step t ;
$Catch_{s,a,f,t}$	=	Catch for stock s , age a , in terminal fishery f , at time step t ;
$Shakers_{s,a,f,t}$	=	Sub-legal mortality for stock s , age a , in terminal fishery f , at time step t ;
$Dropoff_{s,a,f,t}$	=	Non-landed mortality for stock s , age a , in terminal fishery f , at time step t ;
$LegalShakers_{s,a,f,t}$	=	Legal-sized mortality of fish released during mark-selective fisheries for stock s , age a , in terminal fishery f , at time step t ; and
$CNR_{s,a,f,t}$	=	Non-retention mortality (legal and sub-legal sized) for stock s , age a , in terminal fishery f , at time step t .

Other Algorithms and Equations Used in the Model

Adult Equivalency (chinook only). Fishery-related mortality for chinook is expressed as a nominal value or adjusted for “Adult Equivalents” (AEQ) to account for the multiple ages that the fish mature and are vulnerable to fisheries. Fishery-related mortalities are expressed as adult equivalent mortalities so that all fishery mortalities can be expressed in a common unit of measure, which is the number of fish that would have matured (escaped to spawn) in the absence of fishing. The AEQ factors adjust for the natural mortality that would have occurred between the time/age the fish were caught and the time/age that they would have matured or escaped to spawn. The factors used in FRAM are calculated in the CWT base period calibration process and take into account fixed age-specific natural mortality rates and age and stock specific maturation rates which are calculated from CWT recoveries. Stock and age specific AEQ values are

expressed in terms of the expected contribution to the age-5, time step 3 fish, which is the oldest age-class at the final time step for mature fish. The AEQ value at the maximum age and final time-step is 1.0 and all other age/time-step values are a proportion of this value. Note that all age classes have an AEQ value of 1.0 in designated “terminal fisheries” (exploitation rates for chinook are usually expressed in terms of adult equivalent mortality). The AEQ factor is calculated as:

$$AEQ_{s,a,t} = MatRate_{s,a,t} + [(1 - MatRate_{s,a,t}) \times (1 - M_{a,t+1}) \times AEQ_{s,a,t+1}]$$

where $AEQ_{s,a,t} = 1$ for $a = 5$ and $t = 3$ (maximum age and final time step for most chinook stocks).

Proportion Modeled Stocks (for chinook only and calculated using base period data). The “model stock proportion” is a value unique to chinook and is the proportion of the total catch in a fishery that is accounted for by the modeled stocks. These proportion modeled stocks values are calculated during the chinook FRAM calibration process. They are fishery specific and remain constant through all time periods. The coho cohort analysis used to create the model base period exploitation rates include estimates for all stock production regions, thus the proportion modeled stock is assumed to always be 1.0.

$$PropModelStock_f = \frac{\sum_s \sum_a \sum_t Catch_{s,a,f,t}}{TotalCatch_f}$$

where $TotalCatch_f$ = the average total Base Period catch in fishery f .

Total Mortality. Total mortality is used to calculate simple exploitation rates by stock, age (chinook), fishery, and time period. The equations used for chinook and coho, respectively, are:

chinook:

$$TotMort_{s,a,t} = \sum_f (Catch_{s,a,f,t} + Shakers_{s,a,f,t} + Dropoff_{s,a,f,t} + LegalShakers_{s,a,f,t} + CNR_{s,a,f,t})$$

coho:

$$TotMort_{s,t} = \sum_f (Catch_{s,f,t} + Dropoff_{s,f,t} + LegalShakers_{s,f,t} + CNR_{s,f,t})$$

and Total Exploitation Rate is then estimated as:

$$ER_s = \frac{\sum_a \sum_t TotMort_{s,a,t}}{\sum_a \sum_t TotMort_{s,a,t} + \sum_a \sum_t Escape_{s,a,t}}$$

where all components are defined previously.

TERMINAL AREA MANAGEMENT MODULE (TAMM)

The FRAM program interacts with two species-specific (chinook and coho) spreadsheet programs that allow users to specify terminal fishery impacts on a finer level of resolution. The spreadsheet program, TAMM, began with separate sections for each of the six Puget Sound terminal areas (Table 7-1) that are defined in the Puget Sound Salmon Management Plan (1985) for the State of Washington and the Treaty Tribes of Puget Sound. This structure has supported development of unique regional management goals and allows managers the flexibility to analyze and report FRAM model output according to their needs. The chinook TAMM contains the original Puget Sound sections, while the coho TAMM has been expanded to allow report generation for many non-Puget Sound stock groups.

Table 7-1. Puget Sound terminal management regions.

Nooksack-Samish	Skagit
Stillaguamish-Snohomish	South Sound
Hood Canal	Strait of Juan de Fuca

Historically, managers used TAMMs to analyze fishery impacts on individual population components of the larger FRAM stock groupings. The relatively new 1986-1991 coho base period now includes individual Puget Sound populations (61 stocks) at the management level of resolution. Similarly, the expanded Puget Sound coho fisheries are comprehensive; thus coho TAMM now serves more as a recipient of FRAM output for customized report generation. In contrast, chinook TAMM remains a critical element of pre-season Puget Sound modeling, as many populations of management focus need to be “extracted” from the aggregated FRAM stock groupings. Abundance levels of every Puget Sound chinook hatchery and natural population are entered into the TAMM, as are harvest impacts from all Puget Sound fisheries, to allow fishery-specific impact analyses on all the populations of interest.

The current chinook base period data (as in the older versions of the coho base period) aggregates terminal area fisheries for FRAM modeling at a higher level than used for management. Typically chinook FRAM has no individual area freshwater terminal sport fisheries or freshwater net fisheries. The chinook TAMM provides the ability to model the individual Puget Sound marine and freshwater net fisheries by smaller date increments associated with fisheries directed at chinook, pink, coho, chum, or steelhead. In addition, test fisheries and fisheries in sub-areas can be specified. Similarly, the ability to model individual Puget Sound freshwater sport fisheries is also provided. The appropriate chinook TAMM fishery impacts are summed into the terminal fishery definitions used by FRAM to calculate the FRAM fishery scalar inputs.

The TAMM fishery inputs, in addition to a fixed catch, allow for two fishery control mechanisms that are not used by FRAM. The control mechanisms (harvest rates) are percent of terminal area abundance (TAA) and percent of extreme terminal run size (ETRS). Each terminal area has specific rules for calculation of the TAA and ETRS values. Basically, the TAA rules include the escapement of all local area stocks and the terminal catch of all stocks. The ETRS rules include escapement and only the terminal catch of the local area stocks, but for a mixed-stock area an associated non-local stock catch is also calculated by FRAM as a base period proportion of total fishery catch. The derivation of these rules comes from the definitions used in the annual terminal run reconstruction for each of the species. Run reconstruction estimates are used in the calculation of modeling inputs for terminal area fishery impacts under the TAA and ETRS methods. The same run reconstructions may be used to develop in-season run size update models.

The TAA and ETRS methods create a problem for estimating the FRAM fishery scalars because the run size in each terminal region is dependent on the impacts from all the other regions. For example, a decrease in Skagit terminal fisheries results in higher escapement for Nooksack and higher TAA and ETRS values. The fishery impacts in Nooksack terminal fisheries would then be calculated higher which lowers the original Skagit TAA and ETRS values.

An iterative process was developed to solve the problem of simultaneous equations between the terminal areas. The FRAM program reruns the terminal fishery time steps until the difference between the TAMM specified expected fishery impacts and FRAM estimates (calculated from base period exploitation rates) are within $\pm 0.1\%$ of the expected value or the difference is less than one fish. On each iteration the FRAM fishery scalars are adjusted by a proportion that is calculated as the expected value divided by the FRAM estimate for each terminal fishery.

As already discussed, the current FRAM coho base period data has much finer resolution of the terminal area fisheries than does the chinook base period. This is a result of the coho run reconstruction program RRTERM fishery definitions that were used to develop this coho base period data. The coho TAMM fishery definitions are the same as the FRAM terminal fisheries and thus allow direct input for effort base fishery scalars and quota values. An iterative process is still needed for the TAA and ETRS abundance based methods.

The TAMM spreadsheets are used to create most of the output reports needed by fishery managers during the pre-season fishery negotiation processes. This functionality was preserved in the current TAMM spreadsheets to ensure continuity and familiarity with the older versions of the program and to divide the duties and responsibilities for input and error checking during the intense management sessions.

Appendix 1. Chinook FRAM Stocks.

Unmarked Stock #	Stock Name	Abbreviated Name	CWT Broods Included*
1	Nooksack-Samish summer/fall	NkSm FIFi	77,79
3	North Fork Nooksack early (spring)	NFNK Sprg	OOB - 84,88 (N. Fk.)

GLOSSARY

Adult Equivalent (AEQ) - The potential contribution of fish of a given age to the spawning escapement, in the absence of fishing. Because of natural mortality and unaccounted losses, not all unharvested fish contribute to spawning escapement. For example, a two-year-old chinook has a lower probability of surviving to spawn, in the absence of fishing, than does a five-year-old, and these two age classes have different “adult equivalents”.

Base Period - A set of years used to estimate exploitation rates, maturation rates, and stock abundances from CWT data. The years used for the base period differ by species and stock, but range from 1974-1979. Brood years are chosen based on consistent coded-wire tagging, and consistent sampling and fisheries in return years. Some stocks in the model were not tagged during the 1974-1979 period; recoveries of these stocks (called “out-of-base” stocks) are adjusted to account for changes in exploitation rates relative to the base period.

Catch Ceiling - A fishery catch limitation expressed in numbers of fish. A ceiling fishery is managed so as not to exceed the ceiling; actual catch is expected to fall somewhere below the ceiling.

Catch Quota - A fishery catch allocation expressed in numbers of fish. A quota fishery is managed to catch the quota; actual catch is expected to be slightly above or below the quota.

Chinook/Coho Nonretention (CNR) - Time periods when salmon fishing is allowed, but the retention of chinook (or coho) salmon is prohibited.

Cohort Analysis - A sequential population analysis technique that is used during model calibration to reconstruct the exploited life history of coded-wire tag groups.

Cohort Size (initial) - The total number of fish of a given age and stock at the beginning of the fishing season.

Coded-Wire Tag (CWT) - Coded microtags that are implanted in juvenile salmon prior to release. A tagged fish usually has its adipose fin removed to signal tag presence. Fisheries and escapements are sampled for tagged fish. When recovered, the binary code on the tag provides specific information about the individual's tag group (e.g., location and timing of release, special hatchery treatments).

Dropoff Mortality - Mortality of salmon that “drop-off” sport or troll fishing gear before they are landed, and die from their injuries prior to harvest or spawning.

Dropout Mortality - Mortality of salmon that die in a fishing net and “drop-out” prior to harvest or salmon that disentangle from a net while it is in the water and die from their injuries prior to harvest or spawning.

Exploitation Rate (ER) - Catch or total fishing mortality in a fishery expressed as a proportion of the total cohort size in all areas (i.e., the total number of fish in the stock of interest at the beginning of the fishing year).

Exploitation Rate Scalar - A multiplier used to estimate fishery impacts by adjusting the base periods exploitation rates. Exploitation rate scalars can be either stock and fishery specific, or they can be applied to all stocks in a fishery.

FRAM - The Fishery Regulation Assessment Model is a simulation model developed for use in estimating the impacts of Pacific Coast fisheries on chinook and coho stocks of interest to fishery managers.

Harvest Rate (HR) - Catch or total fishing mortality in a fishery expressed as a proportion of the total fish abundance available in a given fishing area at the start of a time period.

Hooking Mortality - Mortality of salmon that are caught and released by sport or troll gear, and die from their injuries prior to harvest or spawning.

Management System Evaluation - An evaluation of how well the model predicts variables of interest (e.g., terminal runs, catch by stock, and stock composition) when pre-season estimates of abundance and fishery catches are used as input data. In other words, given that the model performs adequately, does our preseason decision making process, based on preseason predictions, result in the anticipated outcome?

Marked Recognition Error - the probability that a marked fish will be inadvertently released.

Model Calibration - Model process involving base period data which (1) scales the coded-wire tag recoveries to represent a stock, (2) allocates nonlanded catch mortality to stocks, and (3) reconstruct the cohort in order to compute exploitation rates, maturation rates, and stock abundance.

Model Simulation - Use of the model to vary the calibrated fish population abundance and fishing rates to portray the effects, on the stocks and fisheries, of different sets of regulations.

Nonlanded Catch - This category of fishery-related mortality includes hook-and-line drop-off, net gear drop-out, hooking mortality, and other sources of nonlanded mortality such as unreported or illegal catch.

Nontreaty Fisheries - Fisheries conducted by fishers who are not members of the twenty-four Belloni or Boldt Case Area Tribes.

Preterminal - In FRAM, a “preterminal” fishery is one that operates on both mature and immature fish.

Shaker Mortality - "Shakers": This term represents fish that are released from recreational and troll hook and line fisheries, either because they are outside of the regulatory size limits, because the species is not allowed to be kept, or because the individual fisher chooses, for personal or economic reasons, to release the fish.

Terminal - In FRAM, a “terminal” fishery is one that operates only on mature fish. These fisheries tend to be adjacent to a stock’s stream of origin and harvest returning adult fish.

Terminal Area Management Modules (TAMM) - Spreadsheets external to but integrated with FRAM that are used to: (1) provide input for FRAM simulations regarding projected Puget Sound terminal area catches or stock-specific impacts; (2) compute escapements for Puget Sound stock aggregates; and (3) create output reports that summarize simulated regulations, stock exploitation rates, allocation accounting, and escapement estimates.

Treaty Fisheries - Fisheries conducted by fishers who are members of the twenty-four Belloni or Boldt Case Area Tribes.

Unmarked Recognition Error (or Retention Error Rate) - the probability that an unmarked fish will be retained inappropriately in a selective fishery (e.g. naturally-occurring marks, fisher fails to identify mark, fisher fails to comply with release requirement).

Validation - An evaluation of how well the model predicts variables of interest (e.g., terminal runs, catch by stock, and stock composition) when post-season estimates of stock abundance and fishery catches are used as input data. Validation is intended to evaluate performance of the model. In other words, does the model yield correct stock-specific impacts using, as inputs, actual stock size and fishery catch information.
